(Dated: June 8, 2010; J. Chem. Phys. **132**, 214705 (2010))

Starting from the structure of the (TTM-TTP)I₃ molecular-based material, we examine the characteristics of frontier molecular orbitals using *ab initio* (CASSCF/CASPT2) configurations interaction calculations. It is shown that the singly-occupied and second-highest-occupied molecular orbitals are close to each other, i.e., this compound should be regarded as a two-orbital system. By dividing virtually the [TTM-TTP] molecule into three fragments, an effective model is constructed to rationalize the origin of this picture. In order to investigate the low-temperature symmetry breaking experimentally observed in the crystal, the electronic distribution in a pair of [TTM-TTP] molecules is analyzed from CASPT2 calculations. Our inspection supports and explains the speculated *intramolecular* charge ordering which is likely to give rise to low-energy magnetic properties.

I. INTRODUCTION

The characterization of molecule-based electronic conductors is one of the central issue in the research of molecular crystal systems. Typical materials are TTF-TCNQ and (TMTSF)₂PF₆, where TTF, TCNQ, and TMTSF stand for tetrathiafulvalene, tetracyanoquinodimethane, and tetramethyltetraselenafulvalene, respectively. In (TMTSF)₂PF₆, the first superconductivity behavior in molecular solids has been reported.¹ Recent hot topics in the research of molecular crystals is the realization of charge ordering phenomena.² Since the pioneer work of Su *et al.*³ in polyacetylene, the charge trapping phenomenon has been much studied in Peierls transition issues.⁴ In that sense, quasi-one-dimensional chains have received much attention from experimental and theoretical points of view.⁵⁻⁸ Theoretical approaches that focus on a single highest-occupied-molecular orbital (HOMO) or lowest-unoccupied-molecular orbital (LUMO) have been successful in describing fascinating electronic ordered phase. Such a treatment can be justified since in these conventional systems, the HOMO or LUMO levels are well-separated from the rest of the MOs spectrum.²

Nevertheless, new types of molecular solids have been recently synthesized, for instance, aiming at the metalization of the single-component molecular solids family *M*(tmdt)₂ (*M* = Ni, Au),⁹ where tmdt stands for trimethylenetetrathiafulvalenedithiolate. The molecular extension of the tmdt system is so large that a description based on a single molecular orbital (MO) is questionable. As a matter of fact, *ab initio* calculations have been performed¹⁰⁻¹² and an effective three-band Hubbard model has been proposed and succeeded in describing electronic structures.¹³ In this respect, the quasi-one-dimensional molecular compound (TTM-TTP)I₃,¹⁴⁻¹⁶ where TTM-TTP=2,5-bis(4,5-bis(methylthio)-1,3-dithiol-2-ylidene)-1,3,4,6-tetrathiapentalene looks like a promising candidate to investigate the theory limitation of a single-MO approximation. The presence of an I₃⁻ counteranion is suggestive of formally organic [TTM-TTP]⁺ cations in the crystal structure, i.e., unpaired electrons localized within the organic moieties. The magnetic susceptibility^{17,18} and NMR measurements^{19,20} revealed phase transitions at finite temperature. Insulating and non-magnetic behaviors have been confirmed at low-temperature. Furthermore, based on

Raman-scattering²¹⁻²³ and x-ray measurements,²⁴ it has been suggested that an asymmetric deformation of the [TTM-TTP] molecule occurs and charge disproportionation within the molecule is possible below a transition temperature. This novel charge-ordered (CO) state is different from the conventional CO state² and is called *intramolecular* CO state.²³ This nontrivial phenomena observed in this particular compound may not be described using a single-band description, i.e., the present molecular assembly could give rise to a phenomenon beyond a concept expected from a knowledge of a single molecule although the trigger may be hidden in the properties of multi molecular orbitals. Thus, there is a crucial need for theoretical description to rationalize the origin of such state. The purposes of our study are (i) to show that the energy of singly occupied molecular orbital (SOMO) and that of second-highest-occupied molecular orbital (HOMO-1) are quasidegenerate, (ii) to clarify the origin of this quasidegeneracy using an effective three-fragment model for the [TTM-TTP] molecule, and (iii) to show explicitly that the intramolecular charge ordering actually occurs in the neighboring two-molecular system. With this goal in mind, multireference wave function-based *ab initio* calculations are performed to rationalize the electronic distribution in the (TTM-TTP)I₃ material.

II. MOs OF THE [TTM-TTP]⁺ ION

The [TTM-TTP] organic molecule C₁₄S₁₂H₁₂ is shown in Fig. 1. The atomic coordinates are read from the (TTM-TTP)I₃ 298 K crystal structure.¹⁵ In order to assess the packing influence in the electron trapping phenomenon, we did not perform any geometry optimization. Based on this structure, we performed correlated *ab initio* calculations. This type of approach is very insightful since important information is accessible through a reading of the wave function. In particular, complete active space self-consistent field (CASSCF) calculations have turned out to be very efficient to unravel intriguing electronic distribution in organic radical-based materials.²⁵⁻²⁸ On top of the CASSCF wave functions, second-order perturbation theory calculations (CASPT2) were performed using an imaginary shift of 0.3 a.u. and an ionization potential-electronic affinity (IPEA) shift of 0.0 a.u. The IPEA shift

FIG. 1: [TTM-TTP] molecule (right-top) and energy levels of the isolated [TTM-TTP]⁺ ion from ROHF *ab initio* SCF calculations. The SOMO (u) and HOMO-1 (g) are drawn where the red and blue colors denote the sign of orbital.

aims at correcting the energy differences calculations between states holding different open shells. Since we are dealing with spin states, it would be irrelevant to turn on this parameter.^{29,30} This procedure allows one to incorporate the important dynamical correlation effects to reach a high level of accuracy. All our *ab initio* calculations were performed using the MOL-CAS package³¹ with all electron basis sets contractions for the elements S(7s6p1d)/[4s3p1d], C(5s5p1d)/[3s2p1d] and H(3s)/[1s]. We checked the validity of these particular contractions by including diffuse and polarization functions which did not lead to any quantitative changes.

At room-temperature, the [TTM-TTP] molecule exhibits an inversion center. Thus, the MOs can be classified as *gerade* (g) or *ungerade* (u) according to the symmetry point group. As mentioned before, the (TTM-TTP)₃I₃ material is a charge-transfer salt, consisting of [TTM-TTP]⁺ and I₃⁻ species. In a simple picture, the HOMO of the [TTM-TTP]⁺ ion is half-filled, i.e., SOMO. It has been usually recognized that one may concentrate on this SOMO, ignoring the rest of the spectrum on the assumption that its energy is well isolated from those of the other orbitals as compared to the bandwidth.¹⁶ This is one particular issue we wanted to examine. Thus, semiempirical extended Hückel calculations were first performed.^{32,33} In the following, the SOMO and HOMO-1 will be referred to as the u and g orbitals, respectively (see Fig. 1). The energy separation between the g and u valence MOs (see Fig. 1) is ≈ 0.2 eV, while the bandwidth of the HOMO is ≈ 1 eV.¹⁶ Thus, the effect of the g orbital might not be negligible since it is likely to participate in the intramolecular CO phenomenon expected in the (TTM-TTP)₃I₃ system. In order to clarify the charge distribution, CASSCF calculations were then carried out allowing the occupation of two MOs by three electrons, i.e., CAS[3,2]. This method is known to provide very satisfactory charge distribution as soon as the active space is flexible enough. The g and u MOs are then treated on the same footing and both symmetries states can be examined along these calculations. The CASSCF energy difference between the g and u doublets is ≈ 0.5 eV, confirming the relative proximity of the frontier orbitals. The energy spectrum was finally calculated using a restricted open-shell

FIG. 2: Effective three-fragment model for the u MO (a) and the g MO (b). The three fragments are named as L, R, and C, representing the left, right, and center fragments, and their wave functions are φ_L , φ_R , and φ_C , respectively. The u MO is given by the superposition of φ_L , $-\varphi_C$, and φ_R , while the g MO is made of φ_L and $-\varphi_R$. The mutual interaction between the respective fragments are t_b and t_s , representing the through-bond and through-space interactions, respectively.

SCF (ROHF) procedure. Along these ROHF calculations, three electrons are likely to occupy the frontier MOs u and g. These MOs are likely to be singly occupied or doubly occupied in the CASSCF calculations. In order to position the corresponding energies, we performed a ROHF calculation assuming an average number of electrons in the g and u MOs, i.e., 1.5 electrons. The calculated energy levels in the vicinity of the SOMO are shown in Fig. 1. From this inspection, the SOMO has ungerade character, whereas the HOMO-1 is gerade type in agreement with our extended Hückel calculations. The respective ROHF energies $\varepsilon_u = -8.27$ eV and $\varepsilon_g = -8.69$ eV, while the energy difference between the u and g MOs is ≈ 0.4 eV, a value which is consistent with our extended Hückel estimation. This combined semiempirical and *ab initio* information upon the constitutive unit [TTM-TTP]⁺ raises the relevance of a one-band approach to examine the electronic properties of (TTM-TTP)₃I₃ crystal.

III. EFFECTIVE THREE-FRAGMENT MODEL

In this section, we analyze the chemical origin of the close-in-energy character of the g and u MOs. Let us split the [TTM-TTP] molecule into 3 fragments—L, R, and C—as shown in Fig. 2. The L and R parts represent the left and right parts of the [TTM-TTP] molecule, whereas C corresponds to the ethylene-type bridging moiety. Based on this fragments picture, the u MO displays “bonding” character while the g MO is “anti-bonding”. Therefore, one may wonder why the bonding MO lies higher in energy than the anti-bonding one. Part of the answer can be found in the C group orbital u which is likely to mix in the L-R “bonding” orbital (see Fig. 2). As for the interaction between these fragments, we consider two types of hopping integrals here, namely, t_b and t_s . The former accounts for the through-bond interaction, while the latter represents the through-space interaction. The energy levels of the isolated L and R fragments are identical, and set to ε_0 . On the other hand, the energy level of the isolated C fragment is much lower than the L and R fragments, and we parametrize the energy difference as $\Delta\varepsilon (> 0)$. Using the local orbitals

φ_L , φ_R , and φ_C shown in Fig. 2, the effective Hamiltonian for the 3-fragment model reads

$$\begin{pmatrix} \varepsilon_0 & -t_s & -t_b \\ -t_s & \varepsilon_0 & -t_b \\ -t_b & -t_b & \varepsilon_0 - \Delta\varepsilon \end{pmatrix} \begin{matrix} L \\ R \\ C \end{matrix} \quad (1)$$

First, let us neglect the through-bond t_b interaction. The through-space interaction between the L and R parts results in bonding and antibonding MOs whose energy difference is $2t_s$. This virtual situation is shown in the center of Fig. 3. As soon as the t_b interaction is turned on, the energy of the bonding MO is shifted higher, while the anti-bonding MO remain unchanged due to symmetry constraints. Assuming that $\Delta\varepsilon$ is much larger than $|t_b|$, the eigenvalues read

$$\varepsilon_u \approx \varepsilon_0 - t_s + \frac{2t_b^2}{\Delta\varepsilon}, \quad (2a)$$

$$\varepsilon_g = \varepsilon_0 + t_s, \quad (2b)$$

$$\varepsilon_{u'} \approx \varepsilon_0 - \Delta\varepsilon - \frac{2t_b^2}{\Delta\varepsilon}. \quad (2c)$$

The respective wave functions are given by

$$\varphi_u = \frac{1}{\sqrt{2+a^2}}[(\varphi_L + \varphi_R) - a\varphi_C], \quad (3a)$$

$$\varphi_g = \frac{1}{\sqrt{2}}(\varphi_L - \varphi_R), \quad (3b)$$

$$\varphi_{u'} = \frac{-1}{\sqrt{1+a^2/2}} \left[\varphi_C + \frac{a}{2}(\varphi_L + \varphi_R) \right], \quad (3c)$$

where the quantity a is given by $a \approx (2t_b/\Delta\varepsilon)$. In this picture, the L, R and C fragments wave functions are assumed to be orthogonal which is obviously not a limitation for the description. By comparing Eq. (3) with the u and g MOs shown in Fig. 1, one can conclude distinctly that the wave functions φ_u and φ_g correspond to the u and g MOs, respectively. To scope out the $\varphi_{u'}$ MO which is given in Eq. (3c),

FIG. 3: MOs diagram for the effective three-fragment model of the [TTM-TTP] molecule. As the through-space interaction t_s is turned on, the L and R local orbitals mix in and result in bonding and antibonding MOs (center). Then, the through-bond interaction t_b pushes the bonding MOs higher in energy (right). The identified MOs, u, g, and, u_{inner} , which are obtained from the SCF calculations, are also shown. The respective eigen-energies are given by $\varepsilon_u = -8.27$ eV, $\varepsilon_g = -8.69$ eV, and $\varepsilon_{u_{\text{inner}}} = -19.59$ eV.

FIG. 4: The L and R MOs obtained through a unitary transformation of Eq. (3) by taking $a = 0.25$.

we look into the set of ungerade MOs obtained from the SCF calculations. The in-phase combination u_{inner} of φ_L , φ_R , and φ_C wave functions is shown in Fig.3 and its energy is $\varepsilon_{u_{\text{inner}}} = -19.59$ eV. Since a typical value for $|t_b|$ is of the order of several eV, the latter energy separation fully justifies the approximate expressions given previously. Thus, we can assign the $\varphi_{u'}$ wave function to the u_{inner} MO identified in the SCF calculations.

The ratio $2t_b/\Delta\varepsilon (\approx a)$ was estimated from the charge distribution in the [TTM-TTP]⁺ ion, i.e., so-called Mulliken charges. Based upon the CAS[3,2] wave functions, CASPT2 calculations were performed and the resulting Mulliken charges were estimated. Following the three-fragment model, we summed up the Mulliken charges within each fragment, e.g., $\rho_L = \sum_{i \in L} \rho_i$ where ρ_i is the charge of the respective atoms. In the ground state configuration where the u MO is singly occupied, the Mulliken charges on the respective fragments of the [TTM-TTP]⁺ ion were estimated as

$$\rho_L = \rho_R = +0.634, \quad \rho_C = -0.268. \quad (4)$$

The total charge is $\rho_L + \rho_R + \rho_C = +1$. In order to extract the contribution from the SOMO, we analyzed the charge difference between the cation [TTM-TTP]⁺ and the [TTM-TTP] molecule. The latter exhibits the following Mulliken charges on the respective fragments $\rho_L^0 = \rho_R^0 = +0.149$ and $\rho_C^0 = -0.297$. Thus, the charge differences $\Delta\rho_Z \equiv (\rho_Z - \rho_Z^0)$ ($Z = L, R, C$) were calculated as

$$\Delta\rho_L = \Delta\rho_R = 0.485, \quad \Delta\rho_C = 0.029. \quad (5)$$

This means that the hole is mainly localized on the L and R fragments, whereas the charge on the C fragment remains almost unchanged. By combining the information upon the SOMO [Eq. (3a)] and the numerical data of the charge distribution [Eq. (5)], we can estimate the parameter $a \approx (2t_b/\Delta\varepsilon)$ by using the relations $1/(2+a^2) = \Delta\rho_L$ or $a^2/(2+a^2) = \Delta\rho_C$. Based on this analysis, we find $a \approx 0.25$ and finally the ratio $(t_b/\Delta\varepsilon)$ is ≈ 0.12 . Once the parameter a is determined, the fragment wave functions can be obtained explicitly through the inverse unitary transformation of Eq. (3). The resulting L and R MOs are shown in Fig. 4 and correspond to the φ_L and φ_R local MOs. Since $[(\varepsilon_u + \varepsilon_g)/2 - \varepsilon_{u_{\text{inner}}}] = \Delta\varepsilon[1 + 3(t_b/\Delta\varepsilon)^2]$ [see Eq. (2)], the ROHF eigenvalues $\varepsilon_u = -8.27$ eV, $\varepsilon_g = -8.69$ eV, and $\varepsilon_{u_{\text{inner}}} = -19.59$ eV lead to the effective energy of the C fragment $\Delta\varepsilon \approx 10.6$ eV. Finally, the magnitudes of the through-bond/through-space interactions can be estimated, $t_b \approx 1.32$ eV and $t_s \approx -0.04$ eV. From our evaluation, t_s is almost negligible, and the bonding and antibonding MOs of Fig. 3 are almost degenerated. The

through-space integral is much smaller than the through-bond one, $|t_b/t_s| \approx 28$. Since the energy difference between the u and g MOs is determined from Eq. (2)

$$\varepsilon_u - \varepsilon_g \approx -2t_s + \frac{2t_b^2}{\Delta\varepsilon}, \quad (6)$$

the origin of the quasidegeneracy of the u and g MOs can be clarified in the light of the extracted parameters.

In conclusion, the u and g MOs ordering is completely determined by the relative energetics of this three-piece molecule. The through-space interaction t_s is almost negligible, while through-bond interaction t_b determines the energy spectrum.

IV. INTRAMOLECULAR CHARGE ORDERING

In this section, the interactions between neighboring [TTM-TTP]⁺ cations have been investigated using a dimer extracted from the (TTM-TTP)I₃ crystal. We used the atomic coordinates of the crystal structure at 298 K. If the crystal-structure data at low-temperature phase were available, we may perform more quantitative analysis by combining the geometrical optimization. However, it can be considered that the following results are not affected qualitatively. Since we were not only interested in charge distribution, CASPT2 calculations were also performed to specify the low-energy spectroscopy of the [TTM-TTP]₂²⁺ dimer.

A. “MOs”

First, CASSCF calculations were carried out on the [TTM-TTP]₂²⁺ dimer. These calculations were performed including six electrons in four MOs in the active space (CAS[6,4]) to account for the important static correlation effects. The interactions between the neighboring [TTM-TTP]⁺ ions labeled as **I** and **II** give rise to the effective MOs shown in Fig. 5. Importantly, the dimer exhibits an inversion center and the resulting MOs can be classified into gerade and ungerade. Nevertheless, the inversion center of each individual subunit is lost, which might lead to electron localization within the [TTM-TTP]⁺ building blocks. As expected, the CAS[6,4]SCF frontier orbitals (Fig. 5) consist in the in-phase and out-of-phase combinations of the $\varphi_{L,I}$, $\varphi_{R,I}$, $\varphi_{L,II}$, and $\varphi_{R,II}$ MOs. The $\varphi_{L,I}$ and $\varphi_{R,I}$ are the left (L) and right (R) localized MOs on the subunit **I** (see Fig. 4). A similar definition holds for the subunit **II**.

From the subsequent CASPT2 treatment, the ground state is a gerade singlet, and the active MOs exhibit occupation numbers 2.0, 2.0, 0.9, and 1.1, respectively. Importantly, the occupation numbers of the g₂ and u₂ MOs strongly deviate from 2 and 0, a feature of the open-shell nature of the ground state singlet. The symmetry breaking within each [TTM-TTP]⁺ ion induced by the presence of a second partner leads to a mixing of the orbitals depicted in Fig. 3. This particular mechanism is likely to result in the charge ordering we now wish to examine.

FIG. 5: Valence MOs of the [TTM-TTP]₂²⁺ system obtained from CAS[6,4]SCF *ab initio* calculations upon the singlet state of g symmetry.

B. Mulliken charge

From the CASPT2 calculations performed upon the [TTM-TTP]₂²⁺ dimer, a similar Mulliken charge analysis was carried out to quantify the charge redistribution accompanying the dimer formation. The ground singlet state exhibits the following charge reorganization as compared to the isolated neutral [TTM-TTP] molecule

$$\Delta\rho_L = 0.697, \quad \Delta\rho_R = 0.272, \quad \Delta\rho_C = 0.030. \quad (7)$$

As a major conclusion, the charge on the left (right) fragment is strongly enhanced (reduced), which is a clear indication of the intramolecular charge ordering. Again, the charge on the center fragment C is almost unchanged. The present evaluation based on the two-molecule dimer overestimates the charge difference between the L and R fragments as compared to its value in the crystal, and also the validity of Mulliken charges remains questionable since the fluctuation effects were not included. Nevertheless, this qualitative analysis supports the intramolecular CO state.

C. Low-energy spectroscopy

Our Mulliken charge analysis is suggestive of an intramolecular charge ordering mechanism in the (TTM-TTP)I₃ material. Thus, one may expect a charge localization on the left or right parts of the TTM-TTP building blocks. Such scenario is likely to give rise to magnetic interactions involving either the inner parts (i.e., $\varphi_{R,I}$ and $\varphi_{L,II}$ fragments MOs) or the outer parts (i.e., $\varphi_{L,I}$ and $\varphi_{R,II}$).

Thus, starting from the CAS[6,4]SCF calculations, the low-energy spectroscopy of the [TTM-TTP]₂²⁺ species was inspected. The multi-reference CASSCF wave functions were expanded using a local orbitals basis set $\{\varphi_{L,I}, \varphi_{R,I}, \varphi_{L,II}, \varphi_{R,II}\}$ following the transformation

$$\varphi_{g1} \approx \frac{1}{\sqrt{2}}(-\varphi_{R,I} + \varphi_{L,II}), \quad (8a)$$

$$\varphi_{u1} \approx \frac{1}{\sqrt{2}}(-\varphi_{R,I} - \varphi_{L,II}), \quad (8b)$$

TABLE I: Wave functions decompositions (weights) of the $[\text{TTM-TTP}]_2^{2+}$ low-energy states. The wave functions are expressed in terms of the two hole determinants. CAS[6,4]PT2 energies with respect to the ground state singlet g are given in eV.

	$ \varphi_{L,I}\bar{\varphi}_{R,II}\rangle$ (%)	$ \varphi_{R,I}\bar{\varphi}_{L,II}\rangle$ (%)	$ \varphi_{L,I}\bar{\varphi}_{R,I}\rangle$ (%)	$ \varphi_{L,I}\bar{\varphi}_{L,II}\rangle$ (%)	$ \varphi_{L,I}\bar{\varphi}_{L,I}\rangle$ (%)	$ \varphi_{R,I}\bar{\varphi}_{R,I}\rangle$ (%)	Energy (eV)
Singlet, gerade	84	1	3	9	3	0	$E_0 = 0.00$
	11	27	44	13	5	0	$E_2 = 0.27$
	$ \varphi_{L,I}\bar{\varphi}_{R,II}\rangle$ (%)	$ \varphi_{R,I}\bar{\varphi}_{L,II}\rangle$ (%)	$ \varphi_{L,I}\bar{\varphi}_{R,I}\rangle$ (%)	$ \varphi_{L,I}\bar{\varphi}_{L,II}\rangle$ (%)	$ \varphi_{L,I}\bar{\varphi}_{L,I}\rangle$ (%)	$ \varphi_{R,I}\bar{\varphi}_{R,II}\rangle$ (%)	Energy (eV)
Triplet, ungerade	62	5	0	33			$E_1 = 0.09$
	28	47	2	23			$E_3 = 0.47$
	6	8	70	16			$E_4 = 0.62$

$$\varphi_{g2} \approx \frac{1}{\sqrt{2}}(+\varphi_{L,I} - \varphi_{R,II}), \quad (8c)$$

$$\varphi_{u2} \approx \frac{1}{\sqrt{2}}(-\varphi_{L,I} - \varphi_{R,II}). \quad (8d)$$

Since we are dealing with a six-electron/four-MO system, we performed our analysis in the two-hole/four-MO picture. Schematic representations of the different hole configurations for the singlet and triplet states based on these local orbitals are shown in Fig. 6. Such transformation affords a reading of the different wave functions and the extractions of the relevant information in a valence-bond type analysis. Since $|t_s|$ is relatively small, the left and right moieties within each unit do not significantly overlap. Thus, the previous transformation is almost unitary.

The lowest lying states of the $[\text{TTM-TTP}]_2^{2+}$ species are given in Table I. The ground state is singlet g and consistent with a picture that minimizes the electrostatic energy between the two $[\text{TTM-TTP}]^+$ ions. The comparison between the ground state singlet g and first triplet u is very instructive. In both cases, the wave function is largely dominated by the electronic configurations (84 % and 62 % in Table I for the singlet and triplet states, respectively) involving the inner parts (see Fig. 6). The energy difference affords an evaluation of the intermolecular magnetic exchange interaction :

$$J \equiv E_1 - E_0 \approx 0.09 \text{ eV} \quad (9)$$

A positive value reflects an antiferromagnetic interaction, re-

FIG. 6: Schematic view of the different configurations using a hole picture for the singlet (top) and triplet (bottom), respectively. The subscripts I and II stand for the molecules I and II as depicted in Fig. 5.

sulting from the intramolecular charge ordering. Such a value suggests that the spin gap excitation energy should be ≈ 900 K. The first-excited singlet corresponds to the holes localization within one $[\text{TTM-TTP}]^+$ ion. This is a reflection of an *intermolecular* charge ordering which lies much higher and might not be relevant to describe the low-energy properties of the $(\text{TTM-TTP})\text{I}_3$ material. The energy difference (0.35 eV) between this second excited state (singlet g) and the fourth one (triplet u) supports the strong antiferromagnetic interaction within each subunit. This is a mechanism that involves again intermolecular electron transfer. The low-energy spectroscopy in the $(\text{TTM-TTP})\text{I}_3$ material should be mostly governed by the through-space interdimer magnetic interaction J , which results from the intramolecular charge ordering.

V. SUMMARY AND DISCUSSIONS

In the present paper, we examined the low-energy properties of the $(\text{TTM-TTP})\text{I}_3$ material. Complementary semi-empirical and wave function-based *ab initio* calculations were performed upon the elementary unit and a dimer to investigate the underlying electronic distribution. We showed that the SOMO and HOMO-1 are close in energy and that a one-band picture should be ruled out. A chemical understanding arises from the inspection of the building block and effective parameters extracted from a three-fragment model allowed us to rationalize the quasidegeneracy of the $[\text{TTM-TTP}]$ frontier MOs. From the calculation of a system consisting of two neighboring molecules, the inversion symmetry within each molecule is lost. This result is in agreement with experimental data. Indeed, the intramolecular charge ordering which has been experimentally suggested actually occurs in the two-molecule cluster system. The mixing of the SOMO and HOMO-1 results in an electron trapping which results in a 0.697 / 0.272 on the L / R moieties of the $[\text{TTM-TTP}]^+$ ion. Finally, our *ab initio* calculations suggest that the low-energy of the $(\text{TTM-TTP})\text{I}_3$ material is controlled by a single exchange interaction 0.09 eV, resulting from the charge ordering.

In order to complement our Mulliken charge analysis, we also performed preliminary Raman and infrared (IR) calcu-

lations upon the [TTM-TTP]⁺ unit. It has been observed upon cooling that the Raman 1490 cm⁻¹ band splits into two peaks centered at 1487 cm⁻¹ and 1499 cm⁻¹, where this phenomenon was attributed to the differentiation between the C=C ylidenic bonds, featuring a symmetry breaking.²¹ We used the GAUSSIAN03 package³⁴ on isolated one- and two-molecule systems, and full geometry optimizations were carried out on both systems. The information extracted from the one-molecule system should be compared with the high-temperature regime. In contrast, the two-molecule system is expected to give access to the low-temperature Raman spectrum characteristics. The calculated spectrum of two-molecule system displays two vibrational frequencies, 1522 cm⁻¹ and 1534 cm⁻¹, while that of the 1-molecule system shows a single band at 1535 cm⁻¹. Despite a general blue-shift, this result is in agreement with experimental data, and can be attributed to an intramolecular CO phase accompanying the descent in symmetry within the TTM-TTP units. In this calculation, the [TTM-TTP]₂²⁺ dimer was extracted from the available crystallographic data. A direct comparison with experimental findings would rely on Raman and IR calculations using the low-temperature crystal structure. Unfortun-

nately, the lack of such x-ray data disposes of this strategy.

Throughout this work, we have focused only on the [TTM-TTP] ion and have neglected the effect of the counteranion of I₃⁻. As a matter of fact, it has been pointed out, from X-ray measurement,¹⁸ that the large displacement of the I₃ species occurs in the low-temperature phase. This might yield changes in the electrostatic potential, and possibly the electronic distribution in the [TTM-TTP] ion would qualitatively be modified. This point is to be studied in future work.
